Intraosseous Ameloblastoma with a Prominent Extraosseous Component: Pitfalls in Diagnosis

Original Paper

Abstract For many years, gingival tumors of what appear to be peripherally located intraosseous ameloblastoma (IA) arising from the alveolar bone surface have often been confused with peripheral ameloblastoma (PA) causing resorption of the underlying bone. We analyzed a series of five cases of ameloblastoma that demonstrated a combined PA and IA architecture. The tumor commonly involved the anterior-premolar area, mostly in the maxilla and mainly in middle-aged men. The clinical presentation was an exophytic gingival mass inferior to which was a small bone defect. The predominant extraosseous component showed a papillary gross surface, reflecting the histologic proof of fusion between the submucosal tumor and the surface epithelium. In addition to the PA-like growth pattern, common to all was the presence of neoplastic destruction of the alveolar process, corresponding to an associated radiolucent lesion. This restrained component was acceptable as IA. In two cases, recurrence was observed deep in the alveolar bone with no involvement of the gingiva. These tumors appear to be IA that arose from the marginal alveolar bone and grew preferentially in the gingiva, forming a PA-like appearance. From diagnostic, therapeutic and prognostic points of view, this type of IA should not be confused with PA.

Keywords Ameloblastoma • Gingival tumor • Intraosseous type • Peripheral type

Introduction

Ameloblastoma can be encountered in any area of the jaws from the body of bone through the alveolar crest to the gingiva [1, 2], and between 1 and 10% of cases are reported to occur peripherally [3]. By definition, peripheral ameloblastoma (PA) does not spread beyond the gingival submucosa into the alveolar bone [1, 3]. Thus, the final diagnosis of PA always rests with exclusion of a recognizable intrabony lesion; however, the bone defect may occur to varying degrees, when large enough [4]. It is often confusing whether such lesions are primarily PA that erode into the underlying bone or if superficial intraosseous ameloblastomas (IA) that expand out into the overlying gingiva. Indeed, several reports allowed the diagnosis of PA in the presence of bone destruction indistinguishable from IA [4–12]. Although IA of the alveolar bone surface has been referred to as PA of central origin in Gold’s review [8], the most authors rejected this view and argued that these lesions should be classified as IA [4].

In this article, five cases of ameloblastoma in the alveolar process that demonstrated both central and peripheral involvements are presented. The important clinicopathologic features and the differential diagnosis, as well as a review of the literature, are described.
Materials and Methods

Five cases of ameloblastoma with a combination of PA and IA growth pattern were retrieved from the archives of Tsurumi and Meikai University Hospitals, one of which was previously reported as PA by us [4]. Available clinical records were retrospectively reviewed and the newly prepared hematoxylin and eosin-stained slides were thoroughly examined through sectioning at many levels. This work was approved by the Research Ethics Committees.

Results

Clinical and Radiographic Findings (Table 1 and Figs. 1, 2, 3, 4)

The patients ranged in age from 28 to 75 years with an average of 52 years and all were men. Four cases involved the maxilla and the remaining one was found in the mandible. With the exception of case 5, they had a distinct predilection for the anterior-premolar region, 2 of which involved the incisor area. The average size of tumors was

Fig. 1 Case 3. a Pebbly surfaced mass, axial (b) and coronal (c) CT showing a pocket-shaped bone destruction, d gingival tumor showing multiple connections with the papillary surface epithelium and cupping of the underlying bone (H&E, ×6), e another area showing tumor growth far beyond the root tip (H&E, ×3), f deep-seated tumor nests (H&E, ×40), g isolated tumor follicle surrounded by the compact bone (H&E, ×100)
2.0 cm, ranging from 1.4 to 3.0 cm. Tumors extended in a palatal/lingual direction. The most common sign was a painless gingival swelling of several months’ duration. The lesion appeared as a broad-based, exophytic soft-tissue mass with a granular surface (Figs. 1a, 4a). A focal ulceration was recorded in case 4. Since bony expansion was minimal or none, the tumor was seen composed almost entirely of the extraosseous component which is clinically accepted as representative of the whole lesion.

On plain radiographs, three lesions showed a deep cup-like defect in the marginal alveolar bone (Fig. 2a), and an ill-defined, small radiolucency was found in cases 2 and 5 (Figs. 3a, 4b). Neither displacement nor resorption was visible in the teeth roots. In computed tomography and magnetic resonance imaging, a true invading defect was clearly demonstrated in cases 3 and 5 (Figs. 1b, c, 4c).

Treatment and Follow-up (Table 1)

Three cases were diagnosed preoperatively as ameloblastoma by incisional biopsy and managed by en bloc resection. At surgery, the breakup of the alveolar process was recorded. Although a follow-up period is variable, ranging from 6 months to 8 years, none of them recurred. In cases 1 and 2 that were treated by a combination of simple excision and curettage of tumor bed under the clinical diagnosis of papilloma, recurrence was evident within 2 years. After further marginal resection of the alveolar bone with the removal of lesional teeth, both patients were locally free of tumor for 7 years.

Pathologic Findings (Figs. 1, 2, 3, 4)

In a tissue section whole mount, extraosseous proliferations of ameloblastoma in the gingiva were predominant (Figs. 1d, 2b, 2e, 3b, 4d). All tumors fused with the surface epithelium over a wide area (Figs. 1d, 2b, 3b, 4e). Further examinations of the leading edge of tumor on multiple sections at different levels revealed destructive intraosseous proliferations, mostly at the apical root part of lesional teeth (Figs. 1e, 2d, 2e). Spread far beyond the apex in the surrounding alveolar bone was found in case 3 (Fig. 1e, f), and decalcified bone contained a few outlying tumor nests (Fig. 1g). This histomorphology was recognizable as IA.
Cases 1 and 2 recurred in the bone, but the surface epithelium was intact with no neoplastic change (Figs. 2c, 3d).

Discussion

There are many indications in the literature concerning unsuspected small IA of the tooth-bearing part of the jawbone [2, 4, 13–19]. Given that the surrounding alveolar bone provides more resistance to tumor growth than does the gingiva, infiltrating IA has a tendency to extend into the overlying mucosa, either directly or along the periodontal ligament, once tumor nests penetrate the bony confine. As a result, such IA sometimes appears as a gingival mass lesion without causing any clinically visible expansion of the affected bone, thus producing the illusion of PA [8, 16, 20–23].

The co-existence of intraosseous and extraosseous tumors may cause differential diagnostic problems. Theoretically, IA would be within the bone whereas PA would be against the buccal or lingual bone. Critical to differentiating IA from PA is the identification of an intact cortical bone covering the tumor (Fig. 5). Unfortunately, this decisive finding may be obscured with time through complete loss of thinner cortical plates. As with the cases described here, new imaging modalities are more successful than plain radiographs in evaluating the actual extent of the tumor in the alveolar bone. The root divergence, one of the most characteristic radiographic signs of interradicular IA, is not marked in our cases, probably reflecting their unobtrusive intraosseous growth. Since recurrence is so likely to follow too conservative an operation, the removal of unaffected bone and involved teeth as a bloc is consequently advisable.

With regard to the histogenesis, the rests of Malassez inside or outside the periodontal ligament space may be a potential candidate [2, 24–29]. Such epithelial residues, either in the alveolar bone surface or in the cervical or middle portion of the periodontal ligament, seem likely starting points of our cases. The previous observations that ameloblastomatoid rests appeared later in adult life and tended to increase with age lend credence to the occurrence in an older age range [2, 25–29].

To conclude, the present lesion combines an exophytic growth similar to PA with the presence of IA component ahead of the main gingival tumor. The distinction from PA...
Fig. 4 Case 5. a Exophytic nodular mass, b panoramic radiograph of bone destruction in the alveolar process, c T2-weighted MRI showing intraosseous tumor and mucosal cyst of the maxillary sinus (asterisk), d Scanning view of tumor and associated mucous retention cyst (asterisk) (H&E, ×3), e fusions of submucosal tumor with the gingival epithelium (H&E, ×40)

Fig. 5 Intraosseous ameloblastoma. A 52-year-old man presented with a 2-cm, firm mass on the left mandible, a interradicular radiolucency similar to Fig. 2a, b axial CT showing a thin but intact cortical bone, c and d whole tissue mount showing a peripheral rim of residual bone (H&E, c, ×3; d, ×40)
may therefore become challenging [4, 8, 16, 20–23]. In view of the above summarized features, the diagnosis can not be determined by its extraosseous/intraosseous proportion. The practical approach for the surgeons is that an identifiable intrabony lesion is curious in PA [1, 3, 4], and if observed, either radiologically or clinically during surgery, should prompt consideration of IA. They also draw attention to the co-existence of insidious IA in what seems at first glance to be PA, when larger than 2 cm [4]. If, on histologic diagnosis of clinically presumed PA, there is any doubt that the tumor has proliferated from the gingiva into the underlying bone, the pathologists should re-examine the tumor-bone interface by extensive sampling of the entire specimen.
